

WORCESTER POLYTECHNIC INSTITUTE

A Pathogenesis Screen Using *Caenorhabditis elegans* to Identify Virulence Factors in *Candida albicans*

Major Qualifying Project

Margaret Chiasson, Benjamin Landry, Kurtis McCannell, Kelly Pastor

4/26/2010

Abstract

Fungal infections are a serious public health concern, especially in hospitalized immunocompromised patients, due to a dearth of antifungal agents. We aimed to study fungal pathogenesis and understand aspects of the host-pathogen interaction that makes *Candida albicans* a successful pathogen. Based on the observation that *C. albicans* is able to infect *Caenorhabditis elegans*, causing visible disease and ultimately death, we screened a library of *C. albicans* mutants for changes in virulence. We identified four novel genes that affected virulence: orf19.6713, orf19.1219, *DOT4*, and *ZCF15*.

Acknowledgements

We would like to thank the people who have encouraged and supported us in our endeavor to complete this project. To Reeta Prusty Rao, our tea times together never failed to bolster our spirits and give us the strength to push even in the wake of rampant contamination. Your enthusiasm and deep scientific knowledge have been invaluable assets to us for the past year. To Charu Jain, your contagious good mood and willingness to teach have made coming into lab an enjoyable experience. We could always count on you to steer us in the right direction when we were facing problems, and your positive attitude has never failed to put a smile on our faces. To Jeff, we could always count on you to help us when we needed it. Going into lab would not have been the same without you two, and we are going to miss it. Finally we would like to thank the Fungal Genetics Stock Center for providing the mutant library that made this project possible. Thank you to all the people who have made this last year a truly unforgettable experience.

1. The *Candida albicans* Threat

In recent years, the incidence of fungal infections caused by the opportunistic pathogen *Candida albicans* has escalated, primarily due to the increase of immunocompromised patients and a dearth of antifungal therapies. Under normal circumstances, *C. albicans* lives in a balanced environment in and on the human body with endogenous healthy bacteria. However, it can cause serious infection in the mouth, skin, or uro-genital tract if this balance is disrupted. For example, the use of broad-spectrum antibiotics disrupts the natural bacterial flora, giving *C. albicans* an opportunity to proliferate and cause a serious infection (1). Additionally, neonates or patients undergoing chemotherapy, bone marrow, or organ transplants, and those with AIDS are prime targets for these infections, as their immune systems are compromised. Finally, invasive devices such as catheters, intravenous lines, and implants can also cause serious candidemia (fungal infection in the blood), because *C. albicans* is able to form biofilms on these objects. As a result, it has become the fourth leading cause of systemic blood infections, and its mortality rate is 38% (1). Currently, there are a limited number of antimycotic drugs available to treat these infections, due to toxicity and increasing antimycotic resistance (2).

2. Lack of Treatment for Fungal Infections

There are primarily three classes of drugs to treat fungal infections. The azole class, most notably Amphotericin B, targets the binding and synthesis of ergosterol, a cell membrane component specific to fungi. The problem with this agent is that, although it targets a fungus-specific molecule, it can also affect cholesterol, a main component of human cell membranes which is similar biochemically to ergosterol. Since this drug is utilized in high concentrations to treat candidemia, it is also toxic to human cells. Additionally, the rapid emergence of drug-resistant organisms and fungicidal versus fungistatic activity are also downfalls to this class of drugs. Azoles have been the most widely used drug for many years in treating *C. albicans* infections, but toxicity and resistance have created a demand for the development of alternatives (2).

One of the newer classes of drugs is the echinocandins (trade name – Caspofungin) which targets β-1,3 D-glucan synthase through noncompetitive inhibition. Without this protein, the pathogen is unable to synthesize its cell wall completely (3). Finally, the sordarin class of drugs is a strong inhibitor of *C. albicans* proteins, specifically elongation factor 2. The difference

between this drug and the other two classes is that it inhibits protein synthesis, while the others target outer structural elements of the cell (4). While these classes of drugs have worked in treating infections in the past, resistance and toxicity have become large issues in treating systemic and severe infections. Thus, researchers must continue their search for novel virulence factors which could be targets for new drug therapies.

3. Methods to Identify Virulence Factors

There are two distinct approaches to uncover virulence factors that could be potential targets for drugs. A candidate gene approach tests genes that have the potential of affecting virulence, while another approach is the use of an unbiased screen to sort out genes that affect virulence. An advantage of targeting specific genes is that it uses far less resources to skip ones that are not expected to affect virulence. This allows for more time to be spent investigating the suspected genes in different ways and learning about them. On the other hand, this method requires previous knowledge of the genes in question and imagination as to which could be potential virulence factors, allowing for some key factors to be missed entirely. Performing an unbiased screen is ideal, as every gene that is a factor in the virulence of the pathogen will theoretically be discovered, and knowledge of the organism's mechanisms for virulence could increase significantly. However, the number of target genes makes it difficult to test them as thoroughly. A genome-wide screen is more likely to be limited in its performance and not possible with most pathogens. The development of an unbiased assay for all strains in a gene deletion library is difficult, as the loss of some nonessential genes can affect the subject organism in ways unrelated to virulence. In addition, some virulence factors might not affect certain symptoms or certain host organisms or might affect them in multiple ways. An example is the *C. albicans* gene *IFF4* that encodes a cell wall protein, which works as a virulence factor in that it promotes adherence but as an antivirulence factor *in vivo* in that it makes the pathogen more susceptible to attack by neutrophils by alerting hosts' immune systems (5). Therefore, context of the expression of the gene affects the virulence.

4. Previously Identified Virulence Factors

Virulence factors identified to date fall into two broad categories: genes that affect substrate adhesion, attachment, and initial infection and genes that affect the filamentation

pathway of the organism. The presence of cell surface adhesions allows *C. albicans* to make initial contact with host cells and attach strongly. Once adhered, the pathogen secretes hydrolytic enzymes which function to digest host cell membranes as well as degrade host surface components to reinforce adhesion. Some of the most prevalent of these enzymes are known as the SAP family of proteins, or secreted-aspartyl proteases. Additionally, *C. albicans* is able to undergo cellular morphogenesis between unicellular budding cells (yeast form) and chains of filamentous cells (pseudohyphae or hyphae form). It is argued that hyphal cells promote tissue invasion and find breaks in host epithelia while the yeast form promotes propagation of the organism to the cells and uninfected areas. The ability of the organism to switch between the yeast and filamenting forms allows the organism to invade a variety of body locations, adjust quickly to changes in host environment, and evade immune responses and drug therapies (7). Together, changes in the host environment and the virulence traits described above allow for the invasion and pathogenesis of *C. albicans*.

4.1. Histidine Kinases – *SLN1*, *NIK1*, and *HK1*

Studies have shown that transcription factors are important factors in the morphogenesis of *Candida albicans*, and disruptions in certain genes encoding these transcription factors lead to decreased morphogenesis and attenuated virulence. The morphology of *C. albicans* is a result of mainly environmental factors and signaling pathways that include transcription factors which regulate genes recognized as being induced during hyphal formation. Yamada-Okabe et al. showed that three histidine kinase genes, known as *CaSLN1*, *CaNIK1*, and *CaHK1*, are significant in inducing hyphal formation in *C. albicans* (8). When any of these genes were disrupted, a decrease in hyphal formation and attenuation in virulence were observed in a mouse systemic candidiasis model. These effects were most deleterious in the *cahk1Δ-*/ null mutant, as the survival of the mice increased to 20 days, compared to its parental strain of only 5 days (8).

4.2. Transcription Factors – *EFG1*, *CPH1*, and *CPH2*

In a study by Lane et al. in 2001, it was shown that filamentation, the process which produces the hyphal form of *C. albicans*, is regulated by several pathways which converge and additionally regulate known virulence genes (9). The Efg1, Cph1, and Cph2 pathways regulate the expression of *SAP5* and *SAP6*, genes that encode hydrolytic enzymes which are secreted and

assist in host cell digestion and degradation. These pathways also control the expression of *HWP1*, a gene which encodes a cell wall adherence protein in *C. albicans*.

4.2.1. Effect of *rbt1* and *rbt4*

The Efg1, Cph1, and Cph2 pathways affect the transcription of *RBT1* and *RBT4* (9). In a study by Braun et al., two animal models for *C. albicans* pathogenesis showed that *rbt1Δ*-/- and *rbt4Δ*-/- strains had reduced virulence. Braun and his colleagues utilized rabbit corneal infection studies to show the reduced infection and hyphal penetration caused by these mutants in the corneas of rabbits. Then, they used a mouse systemic model to demonstrate attenuated virulence in the *rbt1Δ*-/- and *rbt4Δ*-/- strains (10).

4.2.2. Effects of Dimorphic Transition

Lo et al. showed that *C. albicans* strains with disruptions in Cph1 and Efg1 could not transform into the hyphal stage and were avirulent in the mouse model (11). Wildtype *CPH1*+/+ *EFG1*+/+ strains produce filamentous hyphae which assist in host epithelial penetration and invasion. However, the double mutant strain cannot produce hyphae and thus remains in the budded, yeast form as shown in Figure 1 below. This strain of *C. albicans* is avirulent.

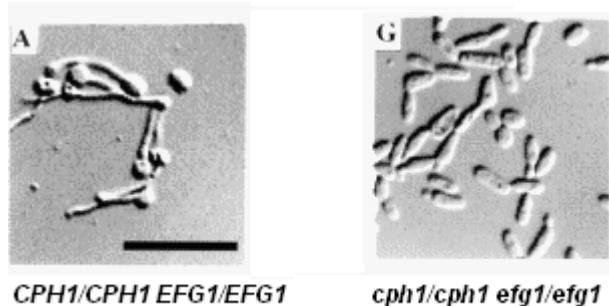

Figure 1: Morphological differences in (A) wildtype (hyphal) and (G) double mutant strains (yeast) of *C. albicans*. Adapted from Lo et al. (11)

Inoculation of 10^4 - 10^6 cells of the double mutant *cph1*-/- *efg1*-/- fails to kill mice while an inoculum of 10^7 cells kills only half the mice after 15 days, compared to the wildtype strain, which kills the mice after 2 days at this concentration (Figure 2). Both mutations are necessary to produce an avirulent pathogen, however single mutations in the gene produce less virulent strains of *C. albicans*.

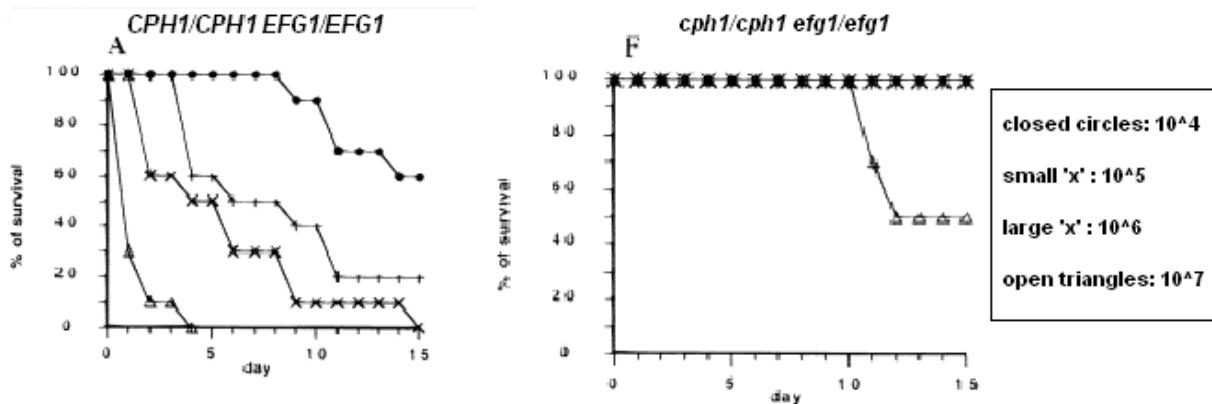

Figure 2: Survival of mice after inoculation with (A) wildtype and (F) double mutant strains of *C. albicans*. Adapted from Lo et al. (11)

Pukkila-Worley et al. demonstrated that *C. elegans* infected with *efgΔ*-/- mutants were attenuated in virulence (12). Additionally, hyphae did not develop in the host throughout the experiment. Although *cphΔ*-/- mutants were unable to make hyphae, they remained virulent upon infection. However, *efgΔ*-/- and *cphΔ*-/- double mutants resulted in remarkable attenuation of virulence in the host (Figure 3) (12).

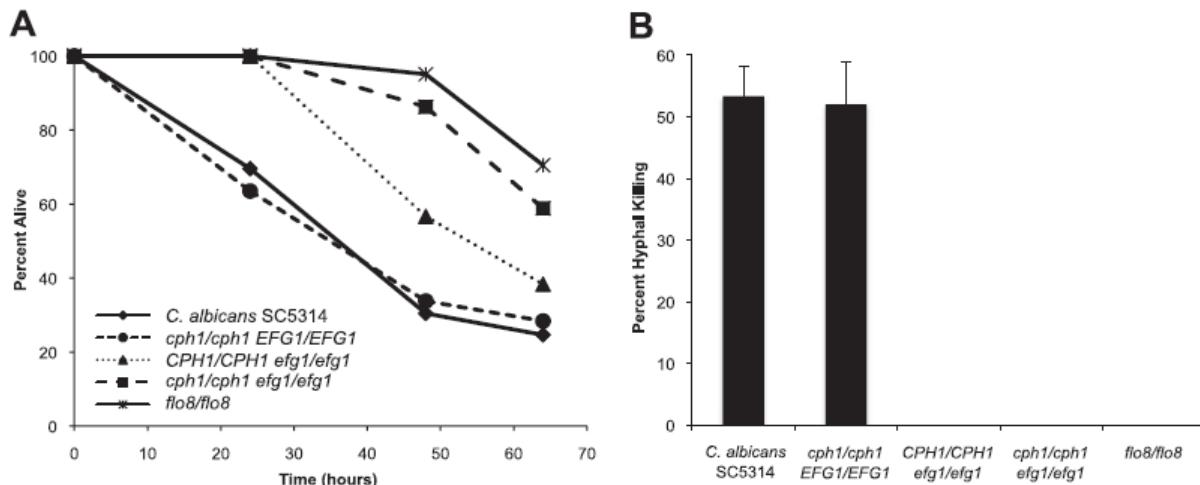

Figure 3: (A) Percent survival of *C. elegans* after infection with wildtype (SC3514) and mutant strains. (B) Percent hyphal killing of wildtype and mutant strains of SC3514. Adapted from Pukkila-Worley et al. (12)

The utilization of multiple pathways to regulate transcription of virulence genes provides an explanation for how *C. albicans* can thrive in various environments and guarantees that the organism can invade and damage host cells. These studies support the idea that transcription

factors are important players in the morphogenesis and subsequent virulence of *C. albicans*, because they amplify the effect of a single gene mutation via a regulatory cascade.

4.3. Cell Wall Proteins

Cell wall proteins (CWPs) are another class of virulence factors that have become important in terms of antifungal drugs. As stated before, CWPs are important for both adhesion and filamentation. It is intuitive that when *C. albicans* is in the hyphal form, it has more surface area to adhere to a host cell. An important group of cell wall proteins in *C. albicans* is the Als (agglutinin-like sequence) family (13). These are large glycoproteins that are involved in the process of adhesion to mammalian cells. Another area of interest is the GPI-anchored cell wall proteins from the Sap (secreted-aspartyl proteinase) family. These proteins are localized in the cell wall and are involved in the adhesion of *C. albicans* to cells (14). Additionally, the Sap enzyme has a role in penetration and invasion by *C. albicans* by degrading components of the host cell membrane.

5. Host-Pathogen Interactions

Genomic virulence screens have previously been powerful tools that allow researchers to uncover the mechanism of infection and better understand an organism's pathogenesis. Many bacterial and fungal organisms have presented a pathogenic threat to humans, so it has been of great scientific interest to understand bacterial or fungal mechanisms of infection. It is also of interest to observe what defense mechanisms the host organism employs to combat the invading bacteria or fungi. Genomic virulence screens allow researchers to identify genes required to infect the host. This information is used to identify specific infection pathways and mechanisms. Many bacterial virulence screens have been performed using the model organisms *Caenorhabditis elegans* and *Drosophila melanogaster* as hosts and the resulting findings have been crucial for the advancement of understanding mechanisms of infection (15, 16, 17, 18, 19, 20, 21).

5.1. *Caenorhabditis elegans*, a Model Host for Virulence Studies

Caenorhabditis elegans has been used as a model host for studying the effects of many pathogenic bacterial species. *C. elegans* is a small nematode with a relatively short life span, 2-3 weeks, which can be grown in a laboratory setting with ease (22). The *C. elegans* genome has

been fully sequenced and can easily be genetically modified either through modification of the wildtype genes or through RNAi knockdown. *E. coli*, the main food source for *C. elegans*, can be modified to express double stranded RNA that is specific to certain *C. elegans* genes, which knock down the gene's protein concentration to a negligible amount (22). Most pathogenic organisms can infect *C. elegans* through physiological means, being eaten by the nematode and moved to the intestinal lumen (23). This allows for the ability to screen many strains of a pathogenic organism without the need for auxiliary techniques such as injection.

Although *C. elegans* is a useful model host for virulence studies, it has its limitations because of its primitive immune system. However, aspects of its innate immune system are conserved in mammals. For example, *C. elegans* contains Toll-like receptors, but they have not been implicated in pathogenic responses (23), because *C. elegans* do not possess an acquired immune system. Therefore, the range of studies on the host side is limited to pathways resulting in cell death or the release of antimicrobial peptides. Since the host innate immune defense is relatively simple, it is possible to study the pathogenic organism's mechanisms for overcoming the host's defenses in order to establish an infection. Despite these limitations, the *C. elegans* model for infection provides a whole animal, genetic model host for rapid mutant screening.

5.2. *Drosophila melanogaster*, Another Model Host for Virulence Studies

Drosophila melanogaster is an established model organism in which innate immunity to fungal and bacterial pathogens is studied (23). *D. melanogaster* has no adaptive immune characteristics, peripheral antigen presenting cells, or B-cells but can mount a swift and powerful immune response to attacking pathogens through Toll and IMD signaling pathways (22). The Toll pathways turn on a cascade of proteins that activate NF- κ B-like transcription factors, while the IMD pathways turn on the Rel family transcription factor Relish (16). Both transcription factors regulate the release of antimicrobial peptides to fight the invading pathogenic organisms. This signaling pathway is homologous to the mammalian cell Toll-like receptor pathway. Therefore, *D. melanogaster* can be used as a powerful model to study innate immunity response mechanisms to various microbial pathogens.

Although *D. melanogaster* is an excellent model for microbial infection, there is a disadvantage in that very few microbial strains will infect it through physiological means. Simply feeding food laced with the pathogenic organism of interest to *D. melanogaster* larvae or introducing the organism onto the exoskeleton will not result in an infection. This problem can

be overcome by introducing the pathogenic organism directly to the thorax with a needle, bypassing *D. melanogaster*'s natural defense and allowing it to cause infection (22). This process restricts the *D. melanogaster* model of innate immunity from being used in assays when many stains of a pathogenic organism are being screened.

5.3. Virulence Screens Using Microbial Pathogens

Several bacterial species have been studied in the context of a pathogenic interaction. An advantage of studying bacteria is that many pathogenic species and strains have been completely sequenced, and genomic databases have been compiled. Also, bacterial genomes can be easily manipulated, and bacteria can be grown without the need for specialized laboratory equipment. Few fungi have been studied in such a manner. One well-studied and well-known fungal pathogen is *Cryptococcus neoformans*, which was demonstrated to infect and kill *C. elegans* by Mylonakis et al. in 2002 (24). This model system using *Cryptococcus neoformans* and *C. elegans* can be used to study infection mechanisms and how they relate to mammalian fungal infections. Genes identified as necessary for infection in a particular fungal species can be used as a basis for pathogenic studies done in a wider range of fungal species by looking at homologous genes.

5.4. Virulence Assay

An assay to rapidly screen for fungal virulence was developed by Jain et al. in 2009 (25). The advantage that this assay has over previous fungal virulence screens using *C. elegans* (25) is that it uses a diseased state, Deformed anal region (Dar), as a measure of virulence instead of death. The length of previous killing assays varied from 5 to >10 days, which would not be conducive for the purpose of screening thousands of genes (24). However, the Dar phenotype assay developed by Jain et al. incorporates a semi-qualitative aspect that is lacking in previous fungal virulence screens and reduces the assay length. The Jain et al. method for virulence detection relies on the *C. elegans* defense mechanism against yeast infection, which results in a Dar phenotype. The severity of the Dar phenotype caused by mutant strains of fungi can be compared to the wildtype strain to gain a deeper understanding of how gene deletions affect the ability of infection. Genes that are responsible for a change in the severity of the infection could lead to the study of lesser known pathways that aid in fungal infections. The method of Jain et al. (25) also reduces the length of the assay to four days, from the plating and hatching of the *C.*

elegans eggs to the appearance of the Dar phenotype (25). This short assay length is useful for the study of deletion libraries that contain a large number of genes. Our project aims to utilize this assay in the search for genes which encode for various virulence factors in *C. albicans*.

6. Experimental Goals

The goals of the virulence assay are dual fold: (1) to further the understanding of how the pathogenic organism *Candida albicans* establishes a successful infection and (2) to identify novel virulence factors as potential drug targets.

The immediate goal of the virulence screen is to further the understanding of the infectious mechanisms of *C. albicans* and how it subverts a variety of the host organism's immune defenses. A deeper understanding of how *C. albicans* is a successful pathogen will allow researchers to predict how it will survive in the host and how a change in environment will affect its ability to establish a successful infection. This knowledge could also be applied to homologous fungal species and allow for the advancement of general fungal knowledge.

Through such a screen, we are able to identify gene mutations in the *C. albicans* genome that hinder or prevent its ability to establish infection in a host organism. Further study of the genes identified will lead to the discovery of pathways and proteins that have the potential to be targeted for antifungal drug treatments. A pathway or protein that is absent in mammalian cells would be deemed a potential drug target for antifungal therapeutics. Development of such alternate ways of treating fungal infections has been recognized as a growing public health need.

7. Materials and Methods

7.1. Strains and Stocks

Stocks of N2 *C. elegans* were maintained at 16°C on Nematode Growth Agar Media (NGM) (26) plates spotted with *E. coli*. Approximately every 7 days a new stock plate was created where at least 3 adult worms were transferred to an *E. coli* spotted plate. Stocks of OP50 *E. coli* and DAY286 *C. albicans* (used as wildtype) were kept at 4°C, streaked on Luria Broth (LB) and Yeast Peptone Dextrose (YPD) plates, respectively. Each mutant strain was stored in liquid media in 96-well plates, as obtained from the Fungal Genetics Stock Center, at -80°C and thawed at room temperature before use.

7.2. Egg Preparation

At least three worms were transferred to an NGM plate spotted with *E. coli* and incubated for four days at 20°C. On day four, the plates were washed with 15 mL of M9 buffer which was transferred to a 15 mL conical tube and centrifuged at 900 x g for 2 minutes. After removing the supernatant, being careful not to disturb the pellet, 15 mL of a 1:4 dilution of commercial bleach (5.25%) containing 0.25 M NaOH was added to the 15 mL conical tube. The tube was gently inverted for 3 minutes and then centrifuged at 2,000 x g for 2 minutes. The supernatant was removed, and the pellet was washed with 15 mL of M9 buffer. The tube was centrifuged at 2,000 x g for 2 minutes, the supernatant was removed, and the pellet was resuspended in 500 µL of M9 buffer. The average number of eggs per µL was calculated by transferring 5 µL of the egg solution to an unspotted plate and counting the number of viable eggs. Assay plates were then spotted with the appropriate volume of the egg solution (approximately 5 µL) to yield 35 to 40 viable eggs per plate. One assay plate was prepared for each mutant strain, along with one for wildtype *C. albicans* (DAY286) with each assay.

7.3. Virulence Assay

Overnight cultures of the *C. albicans* strains to be assayed, DAY286, and *E. coli* (OP50) were grown at 37°C in 3 mL of YPD media (27) for *C. albicans* and LB media for *E. coli*. From each culture, 500 µL were transferred to 1.5 mL microcentrifuge tubes and centrifuged at full speed in a tabletop microcentrifuge for 1 minute. The supernatants were discarded, and the pellets were washed twice by being resuspended in 1 mL of deionized H₂O (dH₂O) and centrifuged at full speed in a tabletop microcentrifuge for 1 minute. After decanting the supernatant, the pellets were centrifuged again, and then any excess water was removed via micropipette. The pellets were brought to final concentrations of 200 mg/mL for *E. coli* and 10 mg/mL for *C. albicans* in dH₂O. Mixtures of 0.5 µL of *E. coli*, 0.5 µL of the appropriate *C. albicans* strain, 10 µL of 50 mg/mL streptomycin, and 9 µL of dH₂O were spotted in the middle of each assay plate.

The plates were incubated at 20°C and observed on days three, four, and five. Worms were counted for the presence or absence of the Dar phenotype, and severity of the Dar phenotype was compared to the DAY286 *C. albicans* positive control. Other observations, such as death and other changes in phenotype or behavior, were also noted. Figure 4 shows a visual representation of the egg preparation and virulence assay.

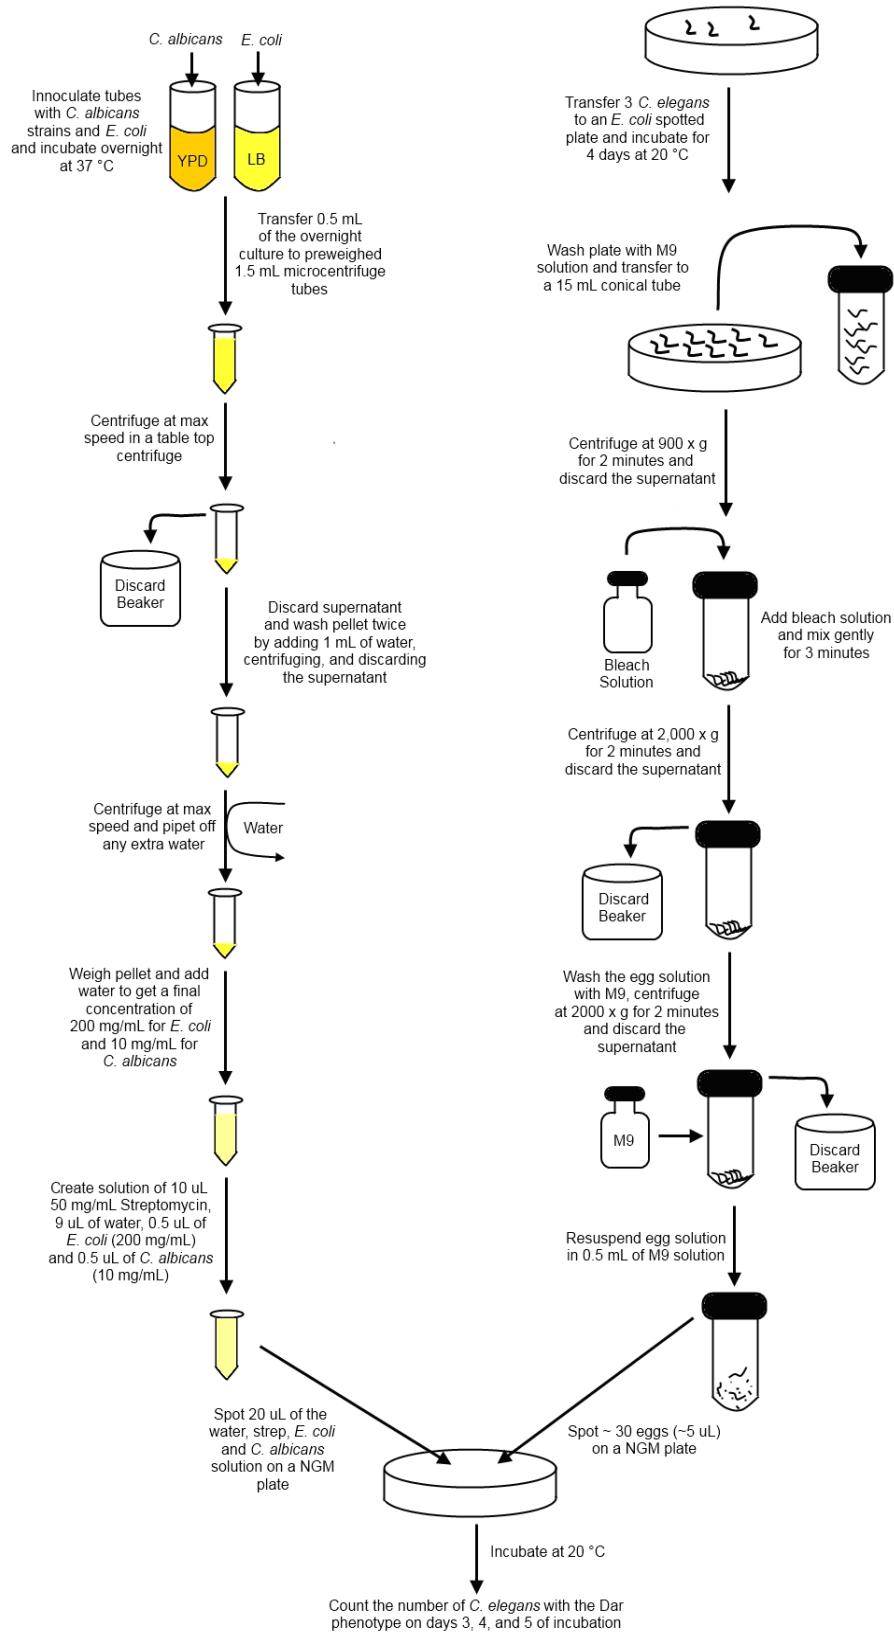

Figure 4: Virulence assay flowchart

7.4. Optimization of the Virulence Assay

The virulence assay used in this study was based on that described by Jain et al. in 2009, with a substitution of *C. albicans* in place of *S. cerevisiae* as the infectious agent. *C. albicans* was chosen as the infectious agent in part because it causes a more pronounced Dar phenotype than *S. cerevisiae* and is a known human pathogen. This substitution necessitated optimization of the new assay to make it high throughput, because of the differences between the two yeast species. *C. albicans* grows at a significantly faster rate than *S. cerevisiae*, so the ratio of *E. coli* to *C. albicans* needed to be adjusted to prevent the *C. albicans* from hindering *E. coli* growth and arresting the *C. elegans* in the L1 and L2 stages. Overgrowth of *C. albicans* also impairs the ability to locate *C. elegans* in the spot. Another concern was that a high concentration of *C. albicans* could induce a false Dar phenotype by overpowering the effects of the gene deletion. Therefore, it was important to adjust the *C. albicans* concentration to get it as low as possible while still showing almost 100% Dar in *C. elegans* plated with wildtype *C. albicans*. After preliminary testing, the concentration of yeast by weight was reduced from the 20 mg/mL of *S. cerevisiae* to 10 mg/mL for *C. albicans*, the amount of each and the *C. albicans:E. coli* ratio were reduced. Sterile water was added to the mixture for spotting the plates in order to further dilute the yeast, to spread it out on the plates.

7.5. Survival Analysis

For survival analysis, plates were prepared in triplicate for each mutant (*dot4Δ*, orf19.1219, and orf19.6713), wildtype (DAY286), and *E. coli* (OP50) as described in the Virulence Assay section. Approximately 30 ± 5 *C. elegans* eggs were spotted on each plate as described in Section 7.2, and the plates were incubated at 20°C. The day prior to a worm transfer, plates would be spotted as described in Section 7.3 and incubated at 20°C for 24 hours. On day 3 of the survival analysis assay, the surviving worms were transferred to a corresponding spotted plate. Every two days, the worms were transferred to a new plate and the number of worms alive, dead, and dead on the edge of the plate were recorded. For data curve analysis, SPSS (IBM, Inc.) was used to generate Kaplan-Meier survival curves and to assess the significance using the Gehan-Breslow test.

8. Results

8.1. Validation of the *C. albicans* Virulence Screen

The pathogenic virulence screen was adapted from the Jain et al. paper (25) with *C. albicans* as the invading pathogen instead of *S. cerevisiae*. To validate that the Dar phenotype marking infection occurred when using *C. albicans*, several optimization experiments were performed. The concentration of *C. albicans*, *E. coli*, and streptomycin were varied prior to the spotting of the assay plates. It was observed that a mixture composed of 0.5 µL of 10 mg/mL *C. albicans*, 0.5 µL of 200 mg/mL *E. coli*, 10 µL of 50 mg/mL streptomycin, and 9 µL of water would yield a spot with optimal *E. coli* and *C. albicans* growth. The spot contains enough *E. coli* to allow the *C. elegans* to progress past their L1 stage of life. Next, the virulence screen assay was performed using the *C. albicans* strain DAY286 to determine whether this strain, the progenitor of the deletion library used in the screen, is capable of causing an infection that produced the Dar phenotype. Worms showing the Dar phenotype were observed on days 3, 4, and 5 with 100% Dar being observed by day 5 (Figure 5). Compared to Dar induced by *S. cerevisiae*, *C. albicans* produced a more prominent protrusion on the anal region of *C. elegans* and appeared in close to 100% of worms on day 3, while Dar caused by *S. cerevisiae* appeared primarily on day 4 of incubation in 80% of the worms.

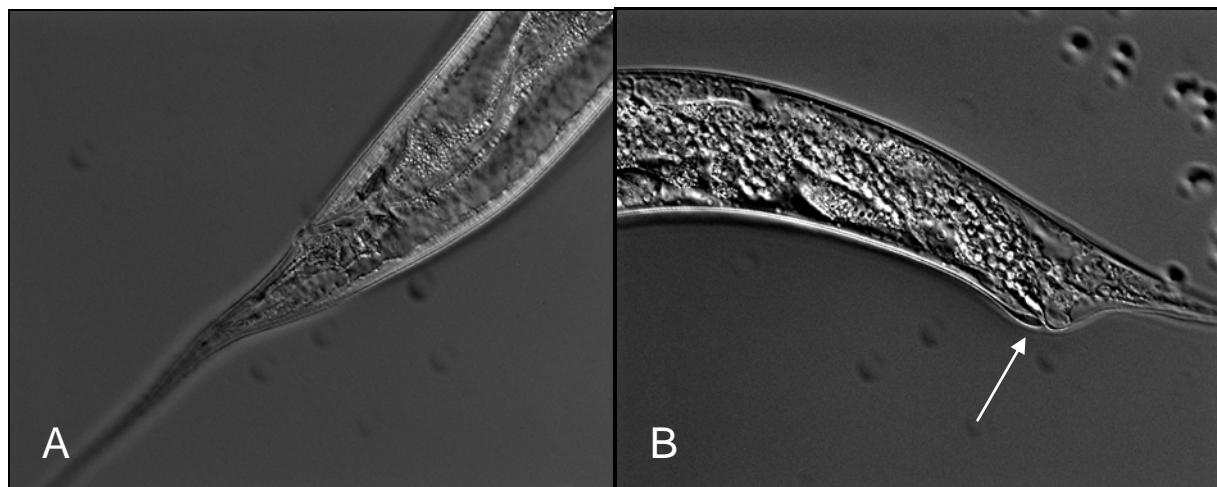

Figure 5: Photographic comparison of the Dar observed in *C. elegans* at 400X magnification, grown on (A) *E. coli* and (B) *E. coli*:DAY286 on day 4. White arrow indicates Dar phenotype.

The virulence screen was further validated by identifying previously known genes that have been associated with virulence in *C. albicans*. The mutant strains *CMP1* (orf19.6033),

SAP8 (orf19.242), and *IFF11* (orf19.12854) showed a reduction in the prominence and presence of Dar over the 3 day observation period (Table 1).

Table 1: Percentage of Dar Phenotype on Days 3, 4, and 5 of Incubation

ORF #	<i>S. cerevisiae</i> Homolog	Day 3			Day 4			Day 5		
		Dar	Total Worms	% Dar	Dar	Total Worms	% Dar	Dar	Total Worms	% Dar
orf19.6033 (<i>CMP1</i>)	<i>CMP2</i>	12	27	44%	14	26	54%	12	25	48%
orf19.12854 (<i>IFF11</i>)	<i>WSC4</i> (best hit)	11	24	46%	10	20	50%	7	11	64%
orf19.242 (<i>SAP8</i>)	<i>YPS1</i> (best hit)	19	28	68%	23	28	82%	25	27	93%

8.2. Identification of Novel Genes

Throughout the screen, four novel *C. albicans* genes were identified as potential virulence factors by a decrease in the presence and severity of the Dar phenotype (Table 2). To determine the function of these novel genes, the *Candida* Genome Database (<http://www.candidagenome.org/>) was consulted to find known orthologs or homologs in *S. cerevisiae*.

Table 2: Novel Genes Associated With *C. albicans* Infection

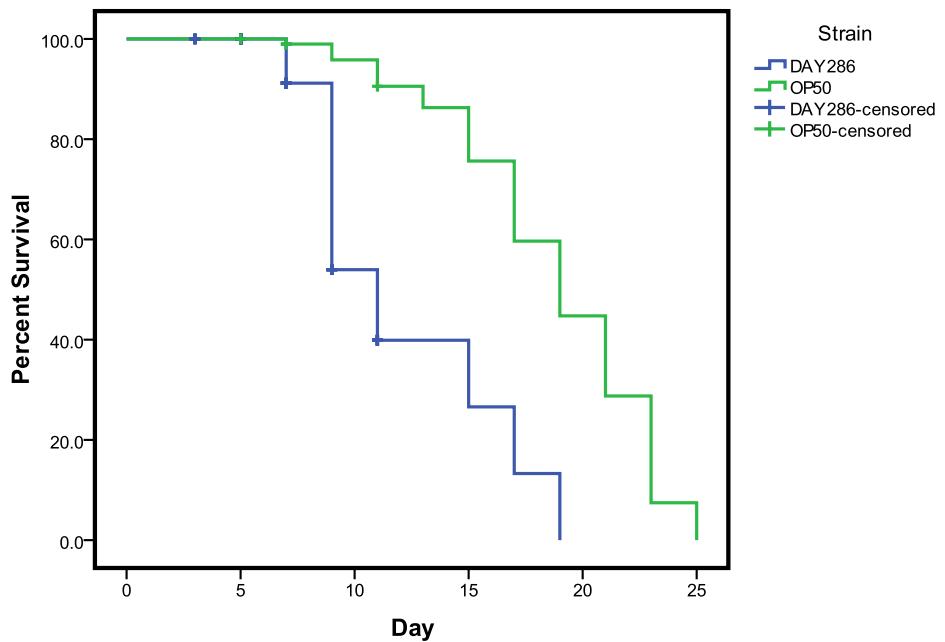

ORF #	<i>S. cerevisiae</i> Homolog	Day 3			Day 4			Day 5		
		Dar	Total Worms	% Dar	Dar	Total Worms	% Dar	Dar	Total Worms	% Dar
orf19.6713	<i>DEF1</i> (best hit)	7	23	30%	6	21	29%	2	20	25%

8.3. Survival Analysis

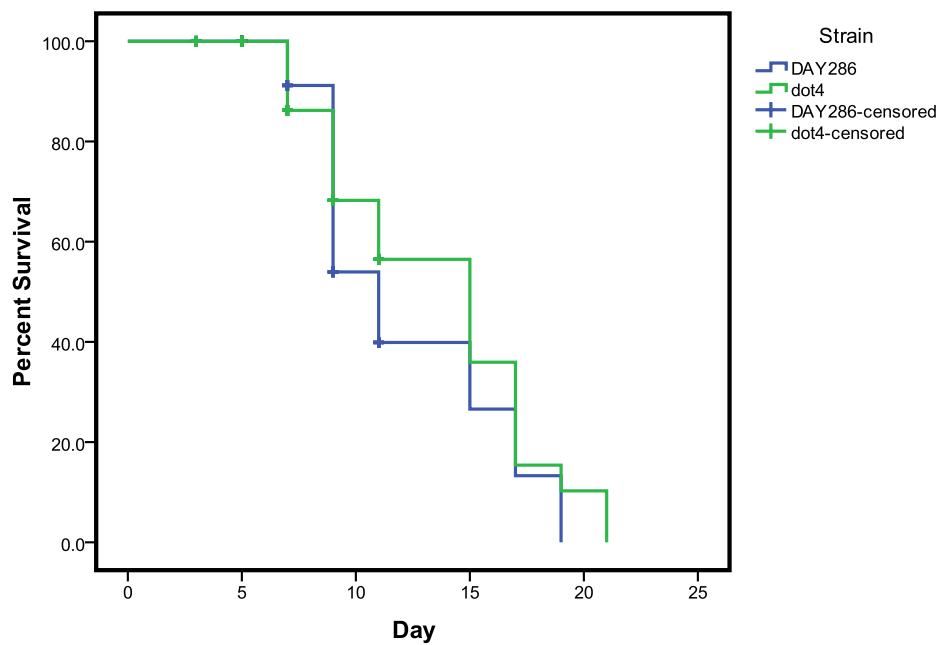

To determine whether the virulence of these mutant strains was affected, they were subjected to a killing assay as described in Section 7.5 in triplicate, along with wildtype. The results of each assay for each strain were combined by addition, and Kaplan-Meier survival curves were generated (Figure 6). With the Grehan-Breslow test, *DOT4* did not show significant deviation from regular *C. elegans* survival ($p>0.05$), but orf19.6713 (*Sc. DEF1*) and orf19.1219

(*Sc. RK1*) did ($p < 0.05$). In the latter strains, the worms survived longer than those grown on wildtype.

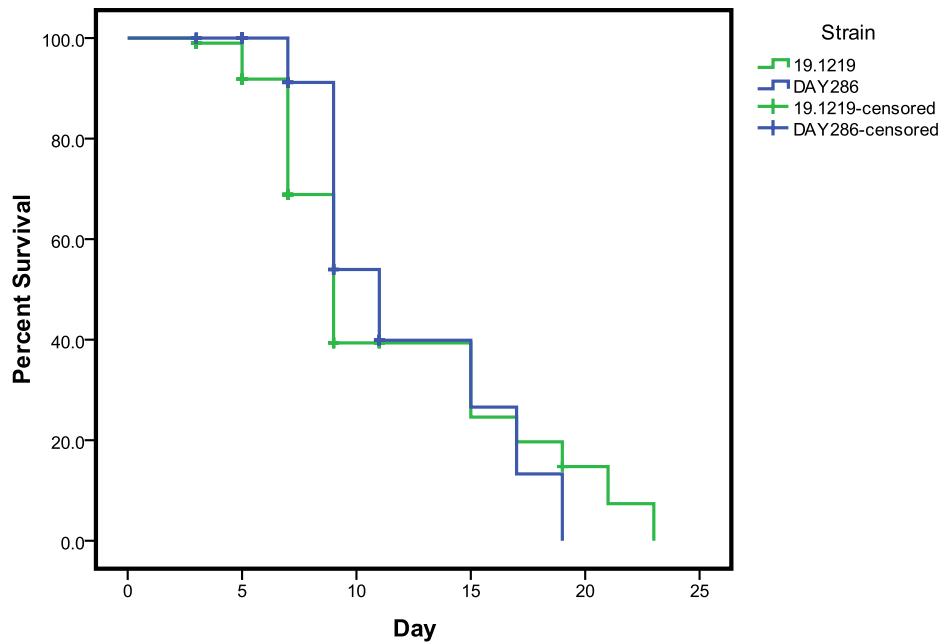

(A) DAY286 and *OP50* ($p < 0.01$)

(B) DAY286 and *dot4* ($p > 0.05$)

(C) DAY286 and orf19.1219 (*Sc. RKRI*) ($p<0.05$)

(D) DAY286 and orf19.6713 (*Sc. DEF1*) ($p<0.05$)

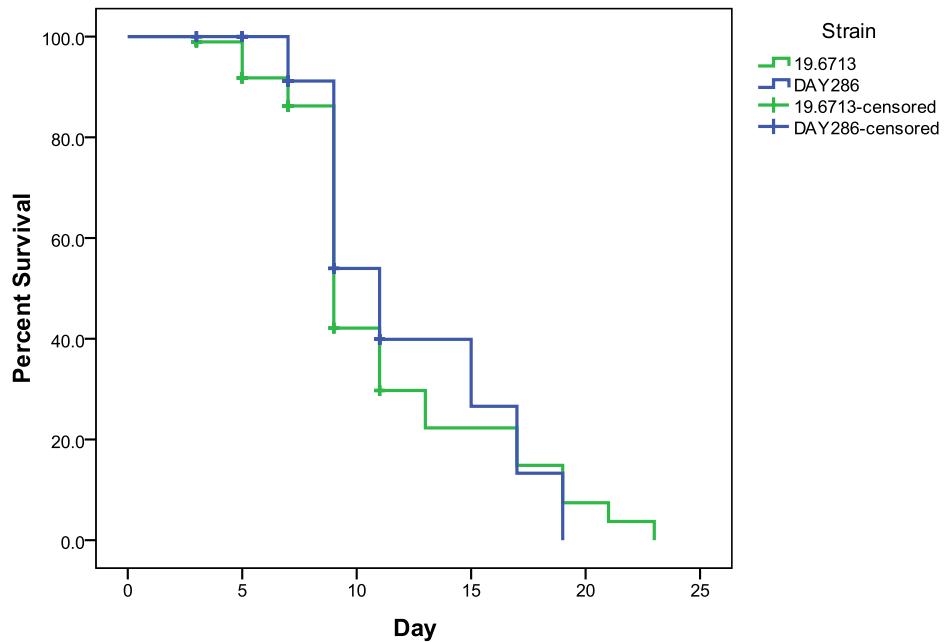

Figure 6: Kaplan-Meier survival curves of (A) only *E. coli*, (B) *dot4*, (C) orf19.6713 (*Sc. DEF1*), and (D) orf19.1219 (*Sc. RKRI*), versus DAY286 *C. albicans*.

8.4. Other Observations

While observing *C. elegans* infected with each mutant, any perceived differences from wildtype in behavior or phenotype besides Dar were also noted. Vulval swelling, as described by Jain et al. (25), was common in worms that were in the later stages of development. The presence of vulval swelling was observed on day 3 of the assay, though it increased over time and appeared to correlate somewhat with the severity of Dar. Interestingly, oral swelling was observed in two worms that were infected with the orf19.1219 mutant during a survival curve assay. No behavioral differences seemed to be significant or common.

9. Discussion

The virulence assay that was developed was determined to be a valid method for identification of virulence factors in *C. albicans*. The Dar phenotype observed in *C. albicans* was similar to that seen in the *S. cerevisiae* model. Observing more prominent and earlier symptoms suggests that *C. albicans* is better at establishing an infection in *C. elegans* than *S. cerevisiae*. This is not unexpected, as *C. albicans* is a pathogen and *S. cerevisiae* is not. In modifying the assay methods for *C. albicans*, a lesser concentration of *C. albicans* is necessary for infection. The *C. albicans* virulence screen was further validated, as it showed a decrease in the severity and presence of the Dar phenotype with mutant strains that were lacking expression of genes that were previously known as virulence factors. This showed that our assay was sensitive enough to detect a partial reduction in virulence.

The genes presented in Table 2 have been identified in our screen as potential virulence factors of *C. albicans*. Mutations in these genes cause a decrease in the number of worms showing the Dar phenotype, which indicates disease. However, based on the screen alone, we cannot speculate as to whether the mutants are more or less virulent. Dar is considered to be protective in that it helps *C. elegans* fight the disease, much like a fever. The mutants can be considered more virulent in the sense that the worms are unable to mount a response against the pathogen to fight the infection, and the fungus rapidly overtakes the worms. On the other hand, the mutants can be considered less virulent in the sense that they do not cause disease at all in the worms, thus showing no Dar. Here, we present information on each of the genes we have identified throughout our screen. We speculate as to how mutations in these genes may affect the virulence of *C. albicans*.

9.1. DOT4

While the function and importance of *DOT4* in *C. albicans* has yet to be studied, evidence from *Saccharomyces cerevisiae* suggests that it plays a significant role in sub-telomeric gene silencing and chromatin modification as a ubiquitin protease (28). Dot4 is primarily located in the nucleus and interacts with the silencing protein Sir4 in order to deubiquitinate histone H2B. As a result of this deubiquitination, methylation of lysine residues 4 and 79 on H3 is prevented, and transcription of genes located near the telomeres is blocked (28, 29).

In *dot4Δ* cells, silencing is disrupted, as the protein is unable to deubiquitinate H2B. The resulting monoubiquitination of H2B results in the methylation of H3, K4, and K79, which leads to open chromatin. Thus, transcription can occur, and genes located near the telomeres are expressed. Since *dot4Δ* cells showed a reduction in the Dar phenotype, it can be surmised that the genes transcribed could affect virulence by influencing dimorphism, adhesion, or an unknown pathway in *C. albicans*. As seen in Figure 6B, there was no significant difference in death rates between *dot4* and wildtype. This could be explained as the sub-telomeric genes that are opened to transcription machinery might not be associated with virulence but rather growth. When these genes are expressed, growth is slowed, and it takes longer to establish a successful infection.

9.2. orf19.1219 (*S. cerevisiae* closest homolog *RKR1*)

The molecular functions and biological processes of orf19.1219 is unknown in *C. albicans*; however, there is information regarding the most similar gene and its protein product in *S. cerevisiae*, *RKR1*. In *S. cerevisiae*, the product of *RKR1* is a conserved nuclear RING domain protein which is a vital component of a protein ubiquitination pathway that modulates chromatin structure, function, and transcription. Rkr1 interacts with Rtf1 to form the Paf1 complex. This complex is required for several histone modifications and transcription elongation (30). Upon the interaction of these two proteins, histone H2B is ubiqutinated, allowing for the methylation of H3 at K4 and K79. As a result of methylation, the chromatin is open, and transcription of the sub-telomeric genes is permitted (31).

Cells lacking functional Rkr1 show impaired sub-telomeric gene silencing (30). In *rkr1Δ* cells, monoubiquitination of H2B K123 is unable to take place, and the histone remains deubiquitinated. As a result, H3, K4, and K79 are not methylated, and the DNA remains tightly

coiled, hindering the ability of transcriptional machinery to dock and transcribe. The genes located near the telomeres are not expressed and thus are silenced. In our study, orf19.1219 cells showed a reduction in the Dar phenotype. This suggests that the genes located near the telomeres may affect virulence by influencing dimorphism, adhesion, or an unknown pathway in *C. albicans*.

9.3. orf19.6713 (*S. cerevisiae* closest homolog *DEF1*)

There is no ortholog of orf19.6713 in *S. cerevisiae*. The closest homolog is *DEF1*, which has its own ortholog in *C. albicans*, *DEF1*/orf19.7561. Studies in *S. cerevisiae* indicate that Def1 has various functions. Previously, it was identified for its role in transcriptional repair and degradation of RNA polymerase II in chromatin. When RNA pol II is stalled at DNA lesions, Def1 forms a complex with Rad26 to enable the ubiquitination and proteolysis of RNA pol II when the DNA is unable to be fixed quickly (32).

Recently, research indicates that Def1 is involved in telomere maintenance. It has been shown to interact with Rrm3, a helicase, to assist in transcriptional elongation of telomeres. In *def1Δ* mutants, telomeres were shortened by approximately 200 base pairs compared to wildtype cells. Yong-Bin et al. shows that this shortening is not a result of a defect in the telomerase recruitment pathway; rather, they argue that Def1 is involved in telomere protection (33). However, there has been no follow-up study describing the mechanism of how this protein functions to protect telomeres.

While *DEF1* has several functions, our working model is that its role in telomere maintenance is most significant to our screen's analysis due to the fact that *DOT4* and *RKR1* play roles in telomere silencing and overall chromatin structure. If the telomeres are not protected as well, it is possible that *C. albicans* will lose its viability over time through damage or a loss of genomic DNA during replication.

9.4. *ZCF15*

In 2005, *ZCF15* was discovered in a screen for zinc cluster proteins. Although its exact function in *C. albicans* has yet to be determined, proteins with zinc cluster domains are generally involved in DNA recognition (34). The closest homolog of *ZCF15* is *PUF2* in *S. cerevisiae* (35). Puf2, along with the other Puf proteins, binds to 3' untranslated regions of mRNAs to modulate expression. Specifically, Puf2 associates with mRNAs encoding membrane proteins as well as

proteins involved in transmembrane transport and vesicular trafficking (36). If *ZCF15* has a similar function, one can speculate that it may modulate expression of certain cell membrane proteins of *C. albicans*. These membrane proteins can include those involved in adhesion or the excretion of hydrolases, thus affecting the virulence of the organism.

9.5. Future Experiments

The first step in further study of the genes identified in our screen is to make mutant strains containing deletions in the genes. The strains in the library utilized in our screen contained transposon-generated mutants. As a result, one cannot be certain that the transposon inserted itself correctly within the gene, causing a disruption. Additionally, it may have inserted itself elsewhere in the genome, and the decreased Dar phenotype could be a result of that disruption. Thus, it is necessary to completely delete each gene in separate strains and reconfirm the decreased Dar phenotype in these strains.

As previously discussed, it is unknown from our screen whether or not the mutants are more or less virulent in causing infection in *C. elegans*. Further experiments are needed to determine whether virulence is amplified or attenuated based on how the genes affect virulence traits of the organism. Two experiments that can be performed easily are filamentation and adhesion assays. One can compare the filamentation and adhesion of wildtype to each mutant strain. A greater amount of filamentation and/or adhesion suggests a more virulent organism, as these are the two main virulence traits of *C. albicans*. A lesser amount of filamentation and/or adhesion will indicate a less virulent organism.

While there were survival curves performed in our research, it would be beneficial to repeat the survival analysis. Since performing the first survival assay, another gene (*ZCF15*) was identified and thus needs to be included in the assay. Survival curves will show whether or not worms grown on the mutant strains can survive longer than worms grown on wildtype *C. albicans*. These results can be related to virulence of strains. For example, if the worms grown on a mutant strain survive longer, it can be hypothesized that the mutant strain is less virulent. If the worms grown on a mutant strain die more quickly than those grown on wildtype, it is suggested that the mutant strain is more virulent. In our initial survival analysis, worms grown on plates with mutant strains orf19.1219 and orf19.6713 survived longer than wildtype, suggesting these mutant strains are less virulent.

Experiments which explore the expression of genes can also be useful for follow-up investigation. A microarray can be a useful tool to utilize, especially in analyzing *DOT4*, orf19.1219, and orf19.6713, as these genes are involved in telomere maintenance. This technique will show which genes are upregulated or downregulated in the mutants in comparison to those expressed in wildtype. Once these genes are identified, one can research what pathways they are involved in and determine more specifically if they are involved in virulence pathways.

While Zcf15 has a domain which generally interacts with DNA, its homolog in *S. cerevisiae*, Puf2, modulates RNA expression. Thus, it must be determined where this protein is functioning in *C. albicans*. A ChIP assay can be utilized to determine if it is binding to DNA and which genes it is affecting if so. Also, the gene *ZCF15* can be sequenced to determine if it contains an RNA-binding domain, as it could potentially bind RNA as well. If the protein is binding to mRNA to modulate expression, an RNA microarray can be useful in determining of which proteins *ZCF15* is enabling or inhibiting the transcription.

Appendix A

This section includes the raw data collected on days 3, 4, and 5 of the assay, showing the number of total worms and the number of worms displaying the Dar phenotype for each strain assayed. Day 3 data is colored purple, day 4 data is colored green, and day 5 data is colored red. Strains that were not assayed contain N/A and are colored blue. All plates used in the assay were obtained from the Fungal Genetics Stock Center (<http://www.fgsc.net/>). The plates are arranged in the following order: CJN TF Plate, 2nd Set TF Plate 1, 2nd Set TF Plate 2, VB GKO Plate 1, VB GKO Plate 2, VB GKO Plate 3, VB GKO Plate 4, VB GKO Plate 5, DS TF Plate, SFY Plate, CWP Plate 1, CWP Plate 2, Miscellaneous Plate, Kinase Plate 1, and Kinase Plate 2.
